A. J. Secchi, Manager  
Solid Propellant Research Operations  
(Von Karman Center)

ABSTRACT

The overall stoichiometries of the ammonia-oxygen and ammonia-chlorine flame reactions have been deduced from mass spectrographic analyses of the gaseous reaction products and from reaction parameters for the opposed-jet diffusion flame. The overall stoichiometry of the ammonia-oxygen flame reaction, in the pressure region of 200 to 760 torr, is best represented by the equation

The volumetric reaction rate ( $\dot{M}_{\text{fu, max}}^{\text{'''}}$ ) and heat release rate ( $\dot{q}_{\text{max}}^{\text{'''}}$ ) for this reaction are  $7.35 \text{ g/cm}^3\text{-sec}$  and  $2.52 \times 10^4 \text{ cal/cm}^3\text{-sec}$ , respectively.

The overall stoichiometry of the ammonia-chlorine reaction at pressures ranging from 300 to 745 torr can be represented by

The volumetric rate of reaction for this equation is  $3.67 \text{ g/cm}^3\text{-sec}$ , which corresponds to a volumetric heat release rate equal to  $9.92 \times 10^3 \text{ cal/cm}^3\text{-sec}$ .

## I. INTRODUCTION

The objective of the research being conducted under this contract, funded by the Advanced Research Projects Agency, is to obtain a better understanding of the mechanisms of combustion, decomposition, and detonation of solids. Current investigations are concerned with the gas-phase reactions associated with the combustion of composite solid propellants and their relationships to the energy transport processes near solid-propellant surfaces.

## II. TECHNICAL STATUS

### A. SUMMARY OF PREVIOUS WORK

The flame reaction between ammonia and chlorine was studied by means of the opposed-jet technique. It was observed that  $\text{NH}_3\text{-Cl}_2$  flames were considerably more difficult to establish than  $\text{NH}_3\text{-O}_2$  and  $\text{NH}_3\text{-NO}_2$  flames. The  $\text{NH}_3\text{-Cl}_2$  flames were too unstable at pressures below 500 torr (nozzle diameter = 0.77 cm) for accurate apparent flame strength (AFS) measurements. The results of AFS measurements indicate that the overall order for this reaction is 2.5 in the pressure range of 500 torr to 1 atmosphere. Furthermore, the apparent flame strength of this system is considerably less ( $\sim 70\%$  less at 1 atmosphere) than that for the  $\text{NH}_3\text{-O}_2$  system in the same pressure range. Other workers predicted that chlorine should oxidize ammonia more rapidly than oxygen. However, at higher pressures, it is believed that chlorine may be the better oxidant.

The volumetric rate ( $\dot{M}'_{\text{fu}, \text{max}}$ ) of consumption of ammonia per unit volume for the reaction

was calculated, on the basis of Spalding's analysis of opposed-jet flames, to be  $5.18 \text{ g/cm}^3\text{-sec}$  at 1 atmosphere. This value corresponded to a volumetric heat release rate ( $\dot{q}'_{\text{max}}$ ) of  $8.5 \times 10^5 \text{ cal/cm}^3\text{-sec}$ .

## B. CURRENT AND PLANNED WORK

The gas-phase reactions which are believed to occur above the surface of burning composite propellants containing ammonium perchlorate (AP) are being investigated. The proposed mechanism (Reference 1) for the degradation of ammonium perchlorate stipulates that the overall kinetic behavior of the  $\text{NH}_3\text{-HClO}_4$  redox flame reaction above the solid surface is governed by at least three competing ammonia oxidation reactions (namely, by  $\text{O}_2$ ,  $\text{Cl}_2$ , and  $\text{NO}$ ). Experimental and theoretical studies designed to test this proposed mechanism are currently in progress. The experimental phase of these studies is being carried out by the opposed-jet technique, which has been described previously (References 2 and 3).

1. Combustion of Ammonia with Oxygen

One aspect of the kinetics problem of determining the rate of heat release from the redox-zone of burning AP involves the determination of the stoichiometry of the pertinent gas-phase reactions. Consequently, product analyses have been carried out to determine the stoichiometry (and exothermicity) of the ammonia-oxygen flame reactions in the immediate region of flame extinguishment.

Table 1 tabulates the conditions and apparent flame strength data for opposed-jet experiments made at pressures ranging from 200 to 745 torr. Table 2 lists the results of mass spectrographic analyses of the reaction products sampled from the effluent streams of several of these ammonia-oxygen flames. The sampling and analytical techniques are such that the values for  $\text{H}_2\text{O}$  concentration are inaccurate; therefore, it is the hydrogen-nitrogen ratio that is utilized in determining the overall stoichiometry of the reaction. Such a procedure is valid since the data indicate that essentially all of the oxygen in the reaction products appears in the water. Also, the data indicate that the  $\text{H}_2/\text{N}_2$  ratio exhibits a small pressure dependency (decreasing with increasing pressure); however, it appears that the product distribution of the  $\text{NH}_3\text{-O}_2$  flame reaction in this pressure region is characterized by a  $\text{H}_2/\text{N}_2$  ratio of approximately 0.5 to 0.6. This conclusion is substantiated by the results of Gaydon and Wolliard (Reference 4) who have calculated the equilibrium compositions and temperatures of  $\text{NH}_3\text{-O}_2$  flames for various mixture strengths. Their calculations

showed that, for a fuel-oxidant ratio of 5/3, the equilibrium  $H_2/N_2$  ratio in the flame was 0.55. This would seem to indicate that chemical equilibrium was attained in the  $NH_3-O_2$  flames examined by means of the opposed-jet technique.

One of the chief features of the opposed-jet technique is that it provides information concerning the fuel oxidant ratio (in the flame) at extinguishment, where the reaction rate is at its maximum. This information has also been used to determine the overall stoichiometry of the  $NH_3-O_2$  flame reaction. The results of an analysis based upon both combustion product analyses and  $NH_3/O_2$  ratios at extinguishment are presented in Table 3. This table lists calculated coefficients for the reactants (based upon product analyses) and for the products, based upon the measured  $NH_3/O_2$  ratios at extinguishment. An examination of the data reveals a slight disparity between the calculated and measured values of the  $NH_3/O_2$  and  $H_2/N_2$  ratios; however, it is clear that the overall stoichiometry of the  $NH_3-O_2$  flame reaction is best represented by the equation

The volumetric reaction rate ( $\dot{M}_{fu, max}'$ ) calculated for this reaction was 7.35 g/cm<sup>3</sup>-sec which corresponds to a volumetric heat release rate ( $\dot{q}_{max}'$ ) of  $2.52 \times 10^4$  cal/cm<sup>3</sup>-sec.

The stoichiometry of the  $NH_3-O_2$  flame reaction postulated earlier in the program (Reference 1) differs from that represented by Equation (1). The previous equation,

was based upon thermodynamic calculations and corresponded to volumetric reaction and heat release rates of 4.81 g/cm<sup>3</sup>-sec and  $2.14 \times 10^4$  cal/cm<sup>3</sup>-sec, respectively. Although the heat release rates are very nearly the same for both cases, the values of the  $NH_3/O_2$  and  $H_2/N_2$  ratios for the latter case do not agree with those determined experimentally.

It should be pointed out that the overall stoichiometry [Equation (1)] determined in these studies does not agree with that determined by others for the  $\text{NH}_3\text{-O}_2$  reaction in non-flame systems. Stephens and Pease (Reference 5) have studied this reaction at temperatures ranging from 525 to 725°C using both flow and static systems. They found that the overall stoichiometry was best represented by the equation

and that the reaction rate reached a maximum near the stoichiometric mixture ( $\text{NH}_3/\text{O}_2$  was slightly less than 1.5). Also, it is well known that maximum flame temperatures are usually obtained with mixtures close to stoichiometric proportions and that maximum reaction rates are expected for mixtures near to this composition. In the case of the  $\text{NH}_3\text{-O}_2$  flame in the opposed-jet, the maximum reaction rate (and heat release rate) does not occur with the stoichiometric mixture ( $\text{NH}_3/\text{O}_2 = 1.5$ ) but with an  $\text{NH}_3/\text{O}_2$  ratio of approximately 1.7. More detailed studies of this reaction in the opposed-jet flame did not disclose a reaction rate anomaly.

#### Combustion of Ammonia with Chlorine

The flame reaction between ammonia and chlorine has not been investigated by means of the opposed-jet technique in conjunction with a mass spectrometer in order to determine the overall stoichiometry of this reaction. Tables 4 and 5 list the reaction conditions and the results of product analysis for flame reactions carried out at pressures ranging from 500 to 745 torr. The data in Table 4 clearly indicate that the mole ratio of ammonia to chlorine, in the vicinity of flame extinguishment, is approximately 2/3 in the pressure region of 350 to 650 torr. The mole ratio values at 500 and 745 torr differ somewhat from the average value of 2.25 because of inaccurate flow rate data. The inaccuracy of these latter data is due primarily to the instability of the ammonia-chlorine flame at these pressures. On the basis of these results (Table 4), the overall stoichiometry can be represented by the equation

which accounts for the measured  $\text{NH}_3/\text{Cl}_2$  ratio of 2.25. However, the results of products analyses (Table 5) indicate that the  $\text{H}_2/\text{N}_2$  ratio in Equation (4) is too high by a factor of about 30. An overall stoichiometry which is in better agreement with the analytical results (neglecting Run No. 41) is represented by the equation

The ammonia-chlorine ratio for this equation is 2.33, which lies well within the experimental error of the extinction measurements. The small amount ( $\sim 2\%$ ) of hydrogen detected in the reaction products is probably due to incomplete reaction of the hydrogen formed in the flame as a result of thermal breakdown of  $\text{NH}_3$  to  $\text{N}_2$  and  $\text{H}_2$  (Reference 4).

The volumetric rate of reaction of ammonia per unit volume for Equation (4) has been calculated on the basis of Spalding's analysis (Reference 1) of opposed-jet flames to be  $3.67 \text{ g/cm}^3\text{-sec}$ . This value corresponds to a volumetric heat release rate of  $\dot{q}_{\text{max}} = 9.92 \times 10^3 \text{ cal/cm}^3\text{-sec}$ . These values and the overall stoichiometry represented by Equation (5) differ from those predicted previously (See Section II of this report).

### 3. Reports and Publications

Three publications describing recent research achievements are currently being prepared. The tentative titles of these papers are as follows:

"The Reactions of Ammonia with Oxygen and Chlorine in the Opposed-Jet Diffusion Flame," by F. J. Cheselske, R. F. Chaiken, and D. J. Sibbett

"Surface Rate Processes and Sensitivity of Solid High Explosives," by R. F. Chaiken and F. J. Cheselske

"Kinetics of the Decomposition of Anhydrous Perchloric Acid," by D. J. Sibbett and I. Geller

The paper by Sibbett and Geller will be submitted for publication in the very near future. A technical memorandum comprising these publications and other pertinent data, will be submitted in lieu of a final report for the year ending February 15, 1964.

h. Future Work

An examination of the reaction between ammonia and the oxides of nitrogen ( $N_2O$ , NO, and  $NO_2$ ) will be initiated in order to provide information needed to define the rate-controlling processes involved in ammonium perchlorate-solid propellant combustion.

A theoretical analysis of the theory of flame strength will be continued.

III. PROJECT PERSONNEL

During the period covered by this report, the following personnel contributed the indicated portions of their time to the program.

	<u>Time, %</u>
F. J. Cheselske, Principal Investigator	100
R. F. Chaiken, Consultant	50
R. S. Dodds, Senior Laboratory Technician	100
